

AN EVALUATION OF DIFFERENT METHODS TO INVESTIGATE ROOT SYSTEM ARCHITECTURE OF URBAN TREES *IN SITU*: I. GROUND-PENETRATING RADAR

by Alexia Stokes¹, Thierry Fourcaud¹, Jiri Hruska², Jan Cermak³, Nadezhda Nadyezhdina³, Valeriy Nadyezhdin³, and Ludek Praus³

Abstract. To evaluate the efficiency of ground-penetrating radar (GPR) to map root systems of urban trees *in situ*, this technique was tested on three trees in an urban environment. After carrying out the extremely rapid GPR tests around the bases of the sample trees, root systems were excavated with an air spade, which produces a supersonic jet of air used to remove soil from roots. Photographs were taken of root system transects for comparison with GPR images. Root system architecture was then quantified for one pine tree, and a two-dimensional image of the root system was reconstructed using AMAPmod software. A comparison of actual roots with images hand drawn from the GPR data showed that the technique is reliable for mapping large roots in the horizontal plane only. Most errors in data from the GPR method were induced when the root systems were manually redrawn, and from roots running parallel to the electromagnetic signal in the vertical plane. These roots could not be identified by GPR. The GPR technique could be considered a valuable nondestructive tool for the arborist, but it still needs development, especially with regard to a software that could reconstruct 3D images of root system architecture from raw data.

Key Words. Ground-penetrating radar; root mapping; architecture; air spade; AMAPmod.

Tree root systems are often considered a major threat to certain structures in urban environments, especially when growing near building foundations and underground utilities such as gas or sewage pipes (Cermak et al. 1997). Insurance companies are subject to increasing numbers of claims from householders and private firms whose buildings allegedly suffer subsidence or structural damage from nearby street trees. However, an efficient and inexpensive method does not yet exist for mapping tree root systems or for identifying the presence of individual large roots. A recent study examined a new nondestructive technique, X-ray computed tomography (Pierret et al. 1999), but this technique is far from being practical enough to be used by the arborist. Using existing and new technology, as well as knowledge from different scientific disciplines, this paper

describes a pilot study to investigate the reliability of one nondestructive method, georadar, for determining the position of individual roots, as well as the architecture of tree root systems *in situ* in an urban environment. Ground-penetrating radar (georadar, GPR) projects high-frequency impulses of energy into the soil from a portable radar system. Energy is reflected back to the surface when the impulse strikes an interface between soil particles (Figure 1). This reflected energy is then recorded on a portable computer. The primary use of GPR has been the identification of compacted soil horizons, stone lines, bedrock, and water tables in soil surveys (Doolittle 1987). The GPR technique is also used by archaeologists for locating buried artifacts. Some of these archaeologists claim that tree roots can also be identified in their GPR images (Cammarano and Piro 1997; Papamarinopoulos et al 1997).

Figure 1. Schematic representation of a portable ground-penetrating radar (GPR) device. Tree roots are detected by an electromagnetic signal, as anomalies in the soil, and this information is transmitted in the form of travel time pulses to a portable computer.

Although mapping tree root systems with GPR has been successfully used and tested in forest and woodland environments, where soil is relatively homogenous (Hruska et al. 1999; Sustek et al. 1999), doubts still exist about the accuracy of this technique in an urban environment. In towns and cities, soil can be extremely heterogeneous and often contains pipes and cables that interfere with signal processing. This method has been used in an urban environment, although not verified by root excavation (Cermak et al. 2000). Several researchers have also tested this technique, although without much success (C. Lohou, pers. comm.; B.C. Nicoll, pers. comm.). These researchers both stated that the main problem with GPR is that it is not possible to tell the difference between underground pipes and stones from roots. However, Hruska et al. (1999) claim that their GPR system has a very high resolution and can even distinguish between water-filled pipes and tree roots.

In this study, the reliability of the GPR technique was tested on urban trees, which were subsequently excavated using an air spade (Rizzo and Gross 2000). Root architecture was then measured and manually digitized (Danjon et al. 1999a, 1999b) to compare two-dimensional root system images with those created by the GPR data.

MATERIALS AND METHODS

Experimental Site and Sample Trees

The experimental site was situated in a garden in the city of Brno, Czech Republic [latitude 49°12', longitude 16°39', altitude 225 m (738 ft)] on a slight (5%) west-facing slope. The site was characterized by a hard and deep loess-clay soil of quaternary origin with a 20% mixture of gravel, covered in places by a shallow layer of lighter soil, mixed with bricks and construction rubble (Cermak et al. 2000). Subsoil was composed of sediments of tertiary origin, Pleistocene loess, torton calcareous clays of montmorillonite type with local occurrence of oncoforous sands (Janovsky 1996). Recent climatic data (monthly means from 1991 through 1996) showed prevailing dry weather in late summer months (Hydrometeorological Institute, Brno).

Three trees were chosen for the evaluation of GPR. One solitary pine (*Pinus nigra* Arn.) and two mountain ash (*Sorbus intermedia* (Ehrh.) Pers.) trees, which were growing at distances of 6 and 20 m (19.7 and 65.7 ft), respectively, from the edge of a 2-m-deep (6.6-ft) ditch, where a large two storey building was situated. The two mountain ash trees were growing at a distance of 2.7 m (8.9 ft) from each other, and thus had interlocking crowns. The smaller mountain ash tree had been damaged by the removal of a 20-cm-wide (7.9-in.) strip of bark along the stem on the

east side, resulting in a wound infected by a saprophytic fungus (*Exidia glandulosa*, Phragmobasidiomycetes).

Ground-Penetrating Radar

Ground-penetrating radar (GPR) measurements were carried out on root systems using the same method used in previous studies (Hruska et al. 1999; Cermak et al. 2000). The trees were surrounded by a 6 × 6 m (64.6 × 64.6 ft) plot of grass around the pine tree, and a 9 × 7 m (96.9 × 75.3 ft) plot around the two mountain ash trees. There was a small stump from a shrub growing in the southeast corner of the examined area around the pine, and two other smaller mountain ash trees and one lime (*Tilia platyphyllos*) tree were growing near the southern edge of the area to be measured around the mountain ash trees. Two small shrubs were also situated close to the northeastern edge of this sampling area. It could therefore be presumed that the GPR signals would detect not only roots of the sample trees but also roots from nearby trees and woody shrubs. This mixture of roots was not an ideal situation for testing GPR on urban tree roots, but it was not possible to find isolated trees whose root systems could be excavated and which could be felled after the experiment.

GPR measurement was performed with a portable signal transmitter and receiver-type pulseEKKO 1000A™ GPR system (Sensors & Software Inc., Mississauga, Ontario) using a signal frequency of 450 MHz, which allows horizontal as well as vertical distances to be distinguished with a precision of 5 cm (2 in.). Roots with a diameter greater than 2 cm (0.8 in.) can be identified down to a depth of 2.5 m (8.2 ft). The instrument was gradually moved over the soil surface along specified grid lines, and vertical "slices" of soil were measured (Figure 1). The profile step was 0.05 m (0.2 ft) along lines 0.25 m (0.8 ft) apart in two perpendicular directions. In total, 301 m (987 ft) of lines were scanned, giving 6,160 records for pine, and 476 m (1,562 ft) with 9,504 records for the two mountain ash trees together.

The effective velocity needed to transfer the radar signal into the soil was $v = 0.085 \text{ m ns}^{-1}$, which was estimated through direct measurements of layer velocities at the site and corresponds to that of loess-clay soil. The file of collected data was then processed and evaluated with the software packages EKKO Tools 4.23 and Reflex 4 (K.J. Sandmeier, Karlsruhe, Germany). Both packages are standard geophysical, namely georadar and seismic, signal-processing packages. With this system of processing, it is possible to evaluate the most interesting features of the cross-section under study and suppress unnecessary informa-

tion (Hruska et al. 1999; Sustek et al. 1999). Objects such as stones, cables, and pipes in the soil can be discriminated against using this software. Selected images of root systems (vertical and horizontal views) derived from the measured data were displayed on the computer screen (Figure 2) and then redrawn by hand.

Air-Spade Excavation

Roots were excavated using an air spade (Air-Spade Technology, Verona, PA, model 150/90), which converts the energy of compressed air into digging power using an ultrasonic thin air stream with a velocity of 2 Machs. The air spade was connected to an Ingersoll-Rand compressor that could output a force of 6×10^5 Pa at a velocity of $0.8 \text{ m}^3 \text{ s}^{-1}$. Only the northern half the root system [18 m^2 (194 ft^2)] of the pine tree was excavated, to a depth of 0.5 to 1 m (1.6 to 3.3 ft), due to a shortage of time. Two perpendicular 1 m^2 (10.8 ft^2) transects (south–north and east–west) were also excavated to a depth of 0.5 m close to the trunk in both *Sorbus* trees. The exact location of building rubble, such as cables and pipes, was also noted. Excavated root systems were marked by a $1 \times 1 \text{ m}$ network made of string, and each transect was then photographed to obtain an accurate optical image that could be compared to the images obtained by GPR.

Digitizing of Root System

To produce highly accurate images of root system architecture, which would complement the photographs taken and allow an easier comparison with images of root systems obtained from the GPR data, the root system of the pine tree was manually digitized. The main reason for digitizing the root systems was that the photographs were taken while standing at a certain height above the root system but without any accurate positioning of the camera above each quadrant. Therefore, root size cannot accurately be de-

termined from these photographs because they may have been taken at an angle. Digitized images also provide quantitative data on root size, orientation, and branching pattern. These data are then used for later processing with software that reconstructs 3D images. The manual digitizing process involves the diameter and orientation from due north being measured every 10 cm (4 in.), along each lateral root and daughter branch $> 1 \text{ cm}$ (0.4 in.), to a depth of 25 cm (9.8 in.). Data were then used as input to the software AMAPmod (©AMAP, CIRAD, France).

The software AMAPmod was used to analyze data, and it can handle branched structure at several scales: root segments, whole roots, and whole root systems. Three-dimensional graphical reconstruction is also possible and is normally used for checking data (Godin et al. 1997; Danjon et al. 1999a, 1999b). However, in this case, only a 2D image was necessary to compare the surface roots with the GPR images.

RESULTS

The GPR technique was rapid, with 99 m^2 ($1,066 \text{ ft}^2$) of ground mapped in about 12 hours. One week was then needed to analyze the data. Excavation of root systems was carried out in only 3 days, despite the hard texture of

Figure 2. Typical ground-penetrating radar (GPR) profile at the experimental site. The X axis corresponds to soil depth, and the Y axis to the position of the GPR on the soil surface. The scan consists of a series of reflections—portions of signal reflected from the ground by various objects such as soil strata surfaces, which are usually continuous or near horizontal lines [e.g., the soil surface (indicated by black bracket) and local bodies (indicated by white arrows)]. Individual roots can be detected by anomalies in the signal diffraction, these anomalies being distinguished by their more or less pronounced hyperbolic shape. This shape is caused by the signal scattering on the target object, which in this case corresponds to individual roots. Arrow number 1 indicates the base of a lateral root, and arrows 2 and 3, a branching or crossing-over of the same root at a distance of 2.2 m (7.2 ft) from the root base.

the soil, especially around the mountain ash trees. The slowest part of the excavation was due to the removal of stones in the soil by hand, which was necessary for every half hour of excavation with the air spade.

The GPR images, drawn by hand from the data, suggested that the pine root system occupied practically all the area examined and that roots extended farther than the studied transects, which is in agreement with observations when the root system was excavated (Figures 3a and 4a). The data illustrated that the trunk was positioned centrally within the root system, which was itself circular in shape. As the roots were excavated to a depth of 0.5 to 1 m (1.6 to 3.3 ft), it could be seen that the root system consisted of two tiers, with most lateral roots in the top 20 cm (7.9 in.) of soil. Between a depth of 20 and 80 cm (31.5 in.), no lateral roots > 2 cm (0.8 in.) in diameter were found (Figure 3b). When the GPR images of the pine root system in the vertical plane (Figure 4b) were compared with field observations (Figure 3b), no similarities in root architecture were found.

The image of the pine root system reconstructed by AMAPmod (Figure 5) was compared to that obtained by GPR (Figure 4a). Two-dimensional images of the root system in the horizontal plane only were compared (Figures 6a, 6b, and 6c). A reasonable likeness existed between the

images with regard to the large lateral roots, except for the absence of one major lateral root that had not been captured on the GPR image (Figure 4a). However, many smaller roots existed on the GPR image that were not present on the image of the reconstructed root system and vice versa. These smaller roots on the GPR image may have been roots growing deeper than 20 cm (7.9 in.), which are not discriminated against in the horizontal plane. It was unlikely that these objects were building rubble such as cables and pipes, because such objects were found and mapped during the root system excavation, yet were not perceived in the GPR root system images. It may be possible that stones were mistaken for roots, but also unlikely, because stones can be discriminated against due to their shape and density. It was, however, impossible to obtain the true root system architecture from the GPR data because GPR was unable to distinguish from crossing-over of roots and branching. Very few second- and third-order lateral roots were present in the horizontal plane (i.e., there was little branching), yet the GPR data suggest that a high amount of branching was present in the pine root system.

The root systems of both mountain ash trees were also mapped using the GPR technique (Figure 7), and although the root systems were excavated, they were not digitized due to lack of time. However, from the photo-

Figure 3. (a) Photograph of an excavated *Pinus nigra* root system in the horizontal plane and (b) a schematic illustration of the root system in the vertical plane. A photograph is not available due to the difficulty in obtaining a clear photograph in this plane. The schematic illustration shows that lateral roots were abundant in the top 20 cm (7.9 in.) of soil, and then again at a depth of 80 cm (31.4 in.). Between these two distances, no lateral roots were found; however, vertical roots were present.

graphs taken of each transect, it can again be seen that large roots are identifiable using GPR, but that smaller root position and root architecture is not accurate (Figures 8a and 8b). Root density appeared to be much higher in both mountain ash trees compared to the pine tree, especially with regard to roots < 2 cm (0.08 in.) in diameter. The root systems of both trees did not overlap, nor did roots of the two trees fuse, which was clear from both the GPR images and the photographs, as well as field observations (Figures 8a and 8b).

Figure 4. (a) Ground plan view of the *Pinus nigra* root system, redrawn from the ground-penetrating radar data. One major lateral root has not been detected by the GPR system. (b) Vertical view of the same root system drawn to the same scale. The GPR image of roots in the vertical plane (b) suggests that lateral roots were present at depths of 0 to 100 cm (0 to 39.3 in.); however, this was not the case in reality (Figure 3b).

DISCUSSION

The GPR technique was relatively easy and rapid to use in the field, provided that an experienced user manipulates the portable radar device and analyzes the data. Data evaluation takes a considerably longer time. Potential interference from building rubble, pipes, and cables could be distinguished from the tree roots because these objects were found and noted during the excavation but were not included in the analysis of GPR data. Aside from the inevitable errors produced by manually redrawing root systems (Sustek et al. 1999), several problems exist with the technique and, in the horizontal plane, are concerned with the accuracy of root size and root system architecture. Although large roots could easily be identified using GPR, smaller roots [< 20 mm (0.8 in.) in diameter] could not, nor could the GPR distinguish between root branching and two roots crossing over each other. More thin roots were seen to be connected to the main root system in the GPR images of pine than was actually the case. However, when the roots were digitized, only lateral roots and their daughter branches could be analyzed with AMAPmod; therefore, much information was lost. Extra roots may appear in the GPR images because data analysis is unable to discriminate against roots at a certain depth; therefore, all roots between 20 and 100 cm (7.8 and 39.3 in.) were present in the images of roots in the horizontal plane.

The GPR technique failed to provide useful information when data in the vertical plane were analyzed. GPR images in the vertical plane did not correspond at all to photographs and field observations taken for the pine tree. Although mountain ash root systems were not fully excavated, it can be assumed that GPR data were not accurate for these roots either. The problem with the technique in the vertical plane is that the radar signal cannot identify objects running parallel to the electromagnetic waves transmitted.

It may be possible to use GPR as a tool for tree diagnostics, with the possibility even of determining the healthiness of roots, by quantifying their internal water content, as suggested by Hruska et al. (1999). However, much more research and calibrating of species with

Figure 5. Two-dimensional reconstruction of the *Pinus nigra* root system (only the northern half of the root system shown) derived from manually digitized architecture data and redrawn using AMAPmod software.

Figure 6. Comparison of one 1 m² (10.8 ft²) transect from the root system of *Pinus nigra*, using images from (a) photograph, (b) GPR data, and (c) 2D reconstruction derived from digitized architecture data. The large lateral roots appear to be detected by GPR, as can be seen from both the photograph and the 2D digitized image.

root health would be needed. As a first step, software should be created that could model root system architecture using GPR data. This software could consider the laws governing tree root architecture, structure, and function for a given species type (e.g., conifer or broadleaf) and could be used to reconstruct the root system instead of it having to be redrawn by hand from the data (Jourdan and Rey 1997; Blaise et al. 2000). A candidate for such software is AMAPmod, which is used to reconstruct 3D images from raw data. AMAPmod is simple to use and not only provides 3D images, but it can be used to analyze data using statistical functions. Other techniques as well may be used in conjunction with such a software; for example, a stereological procedure has recently been used to nondestructively estimate root architecture of the grass *Agropyron cristatum*, which had been grown in a transparent medium (Wulfsohn et al. 1999).

The GPR technique is not cheap, but it may be worthwhile to use on valuable trees or trees in delicate situations where excavation is not possible, such as trees growing near pavements, roads, buildings, on unstable slopes, and possibly also in rapid tree screening schemes. Further development of this technique is possible, and huge advances in the software could be made in order to process root architecture data faster and more accurately. With such software and better object resolution, GPR could one day be considered as a useful, nondestructive, rapid technique for assessing root position, root system architecture, and in the long term, root health.

Résumé. Dans le but d'évaluer l'efficacité du radar de pénétration dans le sol pour cartographier in situ le système racinaire d'arbres ornementaux, cette technique a été testée avec trois arbres localisés dans un environnement urbain. Après avoir mené le test avec le radar de façon extrêmement rapide autour de la base des arbres, le système racinaire a été dégagé avec un Air Spade, un appareil qui produit un jet supersonique d'air pour enlever le sol autour des racines. Des photos de sections transversales du système racinaire ont été prises afin de les comparer avec les images provenant du radar. L'architecture du système racinaire a par la suite été quantifiée pour un pin, et une image bidimensionnelle du système racinaire refaite à partir du logiciel AMAPmod. Une comparaison entre le système racinaire réel et les images faites à la main à partir des données du radar ont démontré que cette technique était fiable seulement pour la cartographie des grosses racines, et sur un plan horizontal uniquement. La plupart des erreurs dans les données avec la méthode du radar ont été faites lorsque le système racinaire a été redessiné manuellement, et aussi lorsque des racines couraient parallèlement au signal électromagnétique selon un plan vertical. Ces racines ne pouvaient alors être identifiées avec le radar. La technique du radar de pénétration dans le sol peut être considéré comme un outil non destructeur valable pour l'arboriculteur, mais elle nécessite encore des améliorations, plus spécifiquement au niveau du logiciel pour reconstruire une image 3-D de l'architecture du système racinaire à partir des données brutes.

Zusammenfassung. Um die Effektivität von Bodenradar (GPR) bei der Erstellung von Wurzelkatastern in Großstädten

in situ zu bewerten, wurde diese Technik an drei Bäumen in einer Großstadt getestet. Nach Ausführung des extrem schnellen Radartests an den Prohebäumen, wurden die Wurzelsysteme mit einem Air Spade (Luftspaten) ausgegraben, wobei durch einen superfeinen Luftstrom die Erde von den Wurzeln geblasen wurde. Das Wurzelsystem wurde fotografiert, um mit den Radaraufnahmen verglichen zu werden. Für eine Kiefer wurde die Wurzelarchitektur quantifiziert und mit Hilfe von AMAPmod Software ein zweidimensionales Image von dem Wurzelsystem erzeugt. Ein Vergleich zwischen den tatsächlichen Wurzeln und den Handzeichnungen nach den Radaraufnahmen zeigte, dass diese Technik für die horizontale Erfassung von Wurzeln zuverlässig angewendet werden kann. Die meisten Fehler entstehen bei der manuellen Darstellung der Wurzeln und bei vertikal verlaufenden Wurzeln, die entlang des elektromagnetischen Signals verlaufen. Diese Wurzeln können nicht durch GPR dargestellt werden. Die GPR-Technik kann ein nützliches Werkzeug für den Arboristen sein, aber es besteht noch Entwicklungsbedarf, besonders bei einer Software, die fehlerfrei in 3D darstellen kann.

Resumen. Con el fin de evaluar la eficiencia de penetración del radar del suelo (GPR) para mapear sistemas de raíces de los árboles urbanos in situ, se probó esta técnica en tres árboles en un ambiente urbano. Después de llevar a cabo las pruebas rápidamente con GPR alrededor de la base de los árboles de muestra, los sistemas de raíces fueron excavados con el Air Spade, el cual produce una inyección supersónica de aire, usado para remover el suelo de las raíces. Se tomaron fotografías de los transectos de las raíces, para comparar con las imágenes del GPR. Se cuantificó entonces el sistema arquitectónico de las raíces para un árbol de pino, y una imagen bidimensional del sistema de raíces utilizando el software AMAPmod. La comparación de las raíces reales con imágenes de los datos del GPR mostraron que la técnica es aplicable para mapear grandes raíces en un plano horizontal solamente. La mayoría de los errores en los datos del método GPR fueron inducidos cuando los sistemas de raíces fueron manualmente redibujados, y de las raíces que van paralelas a la señal electromagnética en el plano vertical. Estas raíces no pueden ser identificadas por el GPR. La técnica GPR puede ser considerada como una valiosa herramienta no destructiva para el arborista. Pero aún necesita desarrollo, especialmente hacia un software que pueda reconstruir imágenes en 3 dimensiones de la arquitectura del sistema de raíces, a partir de los datos tomados.
